INTRODUCTION

Motivation
Fusing synthetic objects with a real context requires believable interaction of real and virtual light to convince an observer that the rendered result is not merely augmented but part of the scene.

Such a mixed reality (MR) system has applications in movie production, advertising of unfinished products or cultural heritage visualization. Current interactive MR systems however often disregard proper lighting entirely or greatly simplify shading, excluding light interaction such as indirect light bounces.

Related Work
Several relighting solutions assume either rigid synthetic objects, static scenery (i.e., photographs) or have no real-time requirement when calculating a GI solution. Attempts have been made to resolve this issue with Instant Radiosity [2,4]. To suppress flickering, a large number of virtual point lights (VPL) is necessary, drastically taxing execution speed. I propose to model virtual and real light in a unified radiance field to avoid performance issues from oversampling and to maintain temporal coherence.

Theoretical Framework
Given a reconstructed real scene with light sources and geometry and a non-emissive object O to insert, we can imagine a snapshot of the radiance field of the real scene I. We can furthermore think of another radiation field with the scene containing O. The difference between both - the Delta Radiance Field - contains the residual light introduced by the additional object as well as antiradiance, compensating for the light which is blocked by it. The expansion of both radiance fields into a Neumann series yields a new linear transport operator which can be used to render an existing radiance field.

Practical Framework
To simulate I and operator Δ of the same scene containing O. The difference between both - the Delta Radiance Field - contains the residual light introduced by the additional object as well as antiradiance, compensating for the light which is blocked by it. The expansion of both radiance fields into a Neumann series yields a new linear transport operator which can be used to render an existing radiance field.

ΔI = ΔL = Lp − Lr = ∑ l∈O TlLl − ∑ l∈O TlLl = ∑ l∈O ∆TlLl.

---

METHOD

Creating the DLPV
- Render an RSM I of the reconstructed scene
- Render an RSM I with the additional object O included
- Direct injection
  - Inject VPLs generated from R into a volumetric texture V as spherical harmonic encoded coefficients → Figure 3a
  - Set current blending mode to subtraction
  - Inject VPLs from R into V → Figure 3b
  - Propagate the existing delta in the volume → Figure 3c
  - Set current blending mode to addition
  - Direct injection
    - Inject direct light at voxels generated from R into V with flux and direction of a real light source
    - Set current blending mode to subtraction
    - Inject direct light at voxels generated from R into V

Reconstruction
- Real light sources
  - Extract a fixed number of point light sources with a variance minimized median cut algorithm from the fisheye image
  - Alternatively track a fixed number of light sources with markers in the camera image
- Real scene
  - Track a manually reconstructed ghosting scene with a marker
  - Estimate simple diffuse albedo parameters with the help of reconstructed real light sources

Practical Framework
- Setup
  - Required hardware → Figure 2
    - RGB-D sensor: view of the scene where object O is inserted
    - Fisheye camera: pointed upwards to record incident real light

Figure 1: Head model (courtesy of Infinite-Realities) inserted into a real scene with one reconstructed light source: (a) a synthetic object is inserted without illumination, (b) visible first bounce around the base as well as low resolution shadow (32 propagations, 512² °VPLs, 1ms per frame), (c) indirect effects without synthetic object for better visualization, (d) visualization of the DLPV (red dots indicate negative values).

---

RESULTS

Observations
- Diffuse indirect bounces are stable and almost free of flickering
- Rendering for the entire pipeline adds approximately twice the injection cost of a regular LPV for direct and indirect light
- Shadows, due to the low resolution of the DLPV, are heavily aliased. Increasing the volume size adds prohibitively large evaluation costs.
- Thin geometry can be covered by an extra voxel, leading to light-/shadow-bleeding. Shadow-bleeding artifacts are more severe due to subtraction of energy from wrong surfaces (e.g., in Figure 1b a thin purple line along the green bag).
- On average the DLPV creation consumes 6ms each frame

Conclusion
Delta Radiance Fields can be used to render real scenes in mixed reality applications with superimposition. The first implementation using DLPVs provides efficient and temporally coherent indirect bounces, but suffers from aliasing and light-/shadow-bleeding due to the coarse volume. I would like to combat these problems with higher resolution volumes and introduce indirect specular bounces using voxel Cone Tracing [1].
